## ABSTRACT

We present results from a 479.7 ks *Chandra* exposure of the Hubble Deep Field North (HDF-N) and its immediate vicinity. In our X-ray image, the deepest ever reported with a 0.5–2.0 keV flux limit of  $\approx 4.9 \times 10^{-17}$  erg cm<sup>-2</sup> s<sup>-1</sup>, we detect four new HDF-N X-ray sources bringing the total number of such sources to 12. The new sources include two optically bright ( $R = 18.3$ – $18.8$ ), low-redshift ( $z < 0.15$ ) galaxies, a Fanaroff-Riley I radio galaxy, and an edge-on spiral hosting either a powerful starburst or a low-luminosity active galactic nucleus (AGN). Notably, we have now detected X-ray emission from all luminous galaxies ( $M_V < -18$ ) with  $z < 0.15$  known in the HDF-N. We have also detected the remarkable  $\mu$ Jy radio source VLA J123642.09+621331.4, which is located just outside the HDF-N and has a likely redshift of  $z = 4.424$ . The observed X-ray emission supports the presence of an AGN in this object, and its X-ray-to-optical flux ratio (i.e.,  $\alpha_{\text{ox}}$ ) is consistent with what is seen for low-redshift AGN.

We have detected X-ray variability from two of the previously known HDF-N X-ray sources, and spectral fitting shows clear evidence for X-ray absorption in the brightest X-ray source in the HDF-N, CXOHDFN J123646.3+621404, a  $z = 0.960$  broad-line AGN with associated Mg II absorption. Stacking analyses of optically bright HDF-N galaxies not individually detected in X-rays have provided estimates of their average X-ray fluxes, and we find that the X-ray luminosities of “normal” spirals at  $z \approx 0.5$  are not more than a factor of  $\approx 3$  larger than those of spirals in the local Universe ( $z < 0.01$ ). This constrains models for the evolution of low-mass X-ray binary populations in galaxies in response to the declining cosmic star-formation rate. Monte-Carlo simulations support the validity of the stacking analyses and show that the *Chandra* Advanced CCD Imaging Spectrometer (ACIS) performs source detection well even with effective exposure times of  $\approx 8$  Ms.

*Subject headings:* diffuse radiation – surveys – cosmology: observations – galaxies: active – X-rays: galaxies – X-rays: general.

## 1. Introduction

We are in the process of performing a deep X-ray survey ( $\approx 1$  Ms) of the Hubble Deep Field North (HDF-N; Williams et al. 1996, hereafter W96; Ferguson, Dickinson, & Williams 2000) and its environs with the *Chandra X-ray Observatory* (hereafter *Chandra*; Weisskopf et al. 2000). This field was chosen because of the excellent radio, submillimeter, infrared, and optical studies already completed (see Livio, Fall, & Madau 1998 and Ferguson et al. 2000 for reviews). The HDF-N itself is the most intensively studied extragalactic patch of sky, and it is one of only two such regions (the other being the Hubble Deep Field South) with high-resolution imaging down to 28–29<sup>th</sup> magnitude in several optical bands. By centering our survey on the HDF-N, we ensure that the best possible data will be available for follow-up of the faintest X-ray sources ever detected.

In Hornschemeier et al. (2000, hereafter H00), we presented the first results for the HDF-N based on 164.4 ks of *Chandra* exposure. These results were extended to 221.9 ks over an area much larger than the HDF-N in Hornschemeier et al. (2001, hereafter H01) and G.P. Garmire et al., in preparation (hereafter G01); eight sources in the HDF-N itself were reported. The total exposure on the HDF-N field has recently been more than doubled to 479.7 ks; these new data have allowed the detection of several additional HDF-N sources and substantially improved the X-ray constraints on the previously detected sources. Here we present the additional sources as well as improved constraints on sources in the HDF-N itself and on one remarkable source in its immediate vicinity.

The Galactic column density along this line of sight is  $(1.6 \pm 0.4) \times 10^{20} \text{ cm}^{-2}$  (Stark et al. 1992).  $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$  and  $q_0 = 0.1$  are adopted throughout this paper. Coordinates throughout this paper are J2000.

## 2. Chandra ACIS Observations and Analysis

### 2.1. Observation Details and Image Creation

The field containing the HDF-N was observed with the *Chandra* Advanced CCD Imaging Spectrometer (ACIS; G.P. Garmire et al., in preparation) for a total exposure time of 257.9 ks on 2000 November 21–23 (167.0 ks; observation ID 1671) and 2000 November 24–25 (90.9 ks; observation ID 2344). The background was stable during the first observation, but there was significant background flaring due to “space weather” during  $\approx 30$  ks of the second observation. During this  $\approx 30$  ks the background was  $\approx 2$  times higher, but this has had little impact on the analysis or results presented here. The HDF-N was placed near the aim point for the ACIS-I array on CCD I3 during both observations. These data were added to the 221.9 ks of data presented in H01; the entire HDF-N was covered for all observations and was kept away from gaps between the CCDs.

Several improvements over the data reduction techniques of H01 have been made. The most

recently processed data from the *Chandra* X-ray Center were used, and the standard  $0.5''$  pixel randomization was removed. CIAO 2.0 tools were used whenever possible in place of some of the custom software used for H01.<sup>1</sup> All data were corrected for the radiation damage sustained by the CCDs during the first few months of *Chandra* operations using the procedure of Townsley et al. (2000); this procedure corrects for both position-dependent gain shifts and event grade changes. The absolute astrometry was determined following the method in §3.1 of H01; absolute X-ray source positions in the HDF-N itself are accurate to  $0.4''$  or better.

We created images from 0.5–8.0 keV (full band), 0.5–2.0 keV (soft band), 2–8 keV (hard band) and 4–8 keV (ultrahard band) using the two event grade sets defined in Table 1; hereafter these will be called the “standard *ASCA* grade set” and the “restricted ACIS grade set.” The use of the restricted ACIS grade set improves our ability to detect faint sources in some cases, as discussed in Brandt et al. (2000) and T. Miyaji et al., in preparation. The basic reason for this improvement is that the restricted ACIS grade set rejects a significantly higher fraction of background events than source events (after correction for the radiation damage). With the restricted ACIS grade set, the average soft-band and hard-band background levels are reduced by 36% and 28% relative to the levels with the standard *ASCA* grade set (see Table 1). For comparison, the bright source CXOHDFN J123646.3+621404 (see below) loses 12% of its soft-band counts and 14% of its hard-band counts when the restricted ACIS grade set is used instead of the standard *ASCA* grade set.

## 2.2. Source Detection and Detection Limits

Source detection was performed with WAVDETECT (Freeman et al. 2001). Our criterion for source detection is that a source must be found with a false-positive probability threshold of  $1 \times 10^{-7}$  in at least one of the four bands using either the standard *ASCA* or restricted ACIS grade sets. The 12 sources found in this manner are listed in Table 2. All photometry in Table 2 is for the standard *ASCA* grade set. In Table 2 we also report results for one remarkable *Chandra* source located just outside the HDF-N, CXOHDFN J123642.0+621331. Figure 1 shows the detected sources in the full, soft and hard bands (the ultrahard-band image is not shown since only two sources are detected). Conservatively treating the eight images searched as entirely independent,  $\lesssim 0.15$  false sources are expected statistically. All sources have been manually inspected to be certain that they are not produced or affected by “cosmic ray afterglows” (*Chandra* X-ray Center 2000, private communication). Finally, images made with other grade set choices (e.g., only ACIS grade 0 events) were searched; no additional sources were detected.

WAVDETECT was also run in the various bands to search for lower-significance counterparts (matching to within  $0.5''$ ) of the highly significant sources already detected at the  $1 \times 10^{-7}$  level in at least one of the four bands; in these runs we used probability thresholds of  $1 \times 10^{-6}$  and  $1 \times 10^{-5}$ .

---

<sup>1</sup>See <http://asc.harvard.edu/ciao/>.

Since the spatial-matching requirement greatly reduces the number of pixels being searched, the statistically expected number of false cross-band matches obtained in this manner is very small. The only two cases where new cross-band matches were found with probability thresholds of  $1 \times 10^{-6}$  or  $1 \times 10^{-5}$  are noted in Table 2.

The “effective exposure time” per source, as derived from our exposure map, ranges from 444–464 ks (see H01 for discussion). Even with these long exposure times, the *Chandra* ACIS is entirely photon limited for point-source detection near the aim point. For a power-law model with photon index  $\Gamma = 1.4$  and the Galactic column density, our  $\approx 5$  count detection limit corresponds to soft-band and hard-band flux limits of  $4.9 \times 10^{-17}$  erg cm $^{-2}$  s $^{-1}$  and  $2.3 \times 10^{-16}$  erg cm $^{-2}$  s $^{-1}$ , respectively.

### 2.3. Variability Testing

We have checked all sources for count-rate variability using Kolmogorov-Smirnov (K-S) tests, and the results are reported in Table 2. Such testing is statistically valid even when the number of counts is small, although clearly the sensitivity of the K-S test is reduced when only a few counts are available. Use of the K-S test avoids “a posteriori” selection problems as discussed by Press & Schechter (1974). The testing is always performed in the band where a source has its highest signal-to-noise ratio, and the standard *ASCA* grades were used in this analysis. We have used  $3'' \times 3''$  apertures for count extraction; these are appropriate since the HDF-N was kept close to the aim point for all observations. Gaps between observations were accounted for in the testing.

The two sources showing statistically significant evidence for variability are discussed in §3.2.

## 3. Results

### 3.1. Newly Detected Sources

Figure 2 shows the *Chandra* sources detected thus far overlaid on the W96 HDF-N image, and Table 3 gives the identification information for these sources. Below we describe the properties of the newly detected sources.

*CXOHDFN J123642.0+621331*: This X-ray source lies just outside the HDF-N itself and is positionally coincident with the remarkable  $\mu$ Jy radio source VLA J123642.09+621331.4 (e.g., Richards et al. 1998; Garrett et al. 2001). Detailed studies of this source indicate a redshift of  $z = 4.424$  (Waddington et al. 1999; R.A. Windhorst 2001, private communication; but also see §2.2 of Barger, Cowie, & Richards 2000); we shall adopt this redshift throughout the rest of the discussion below as the other redshift possibilities appear less likely. This source is thought to be powered by either a dust-enshrouded AGN or an ultraluminous starburst. If the redshift is correct,

then this is the most distant X-ray source detected thus far in our *Chandra* field and the ninth most distant cosmic object detected in X-rays (after seven quasars and one gamma-ray burst). The 0.5–2.0 keV observed-frame bandpass in which VLA J123642.09+621331.4 is most clearly detected corresponds to a rest-frame bandpass of 2.7–10.8 keV. The implied luminosity in this bandpass of  $\approx 2 \times 10^{43}$  erg s $^{-1}$  strongly supports the presence of an AGN.

In Figure 3 we compare the AB<sub>1450</sub> magnitude (AB<sub>1450</sub>  $\approx$  25.2 from Figure 3 of Waddington et al. 1999) and 0.5–2.0 keV flux of VLA J123642.09+621331.4 with those of  $z > 4$  AGN observed in X-rays (see Kaspi, Brandt, & Schneider 2000 and Brandt et al. 2001). VLA J123642.09+621331.4 is both the optically faintest and X-ray faintest  $z > 4$  AGN detected in X-rays; it provides the best constraints to date upon the X-ray properties of moderate-luminosity  $z > 4$  AGN. In fact, to our knowledge VLA J123642.09+621331.4 has the lowest optical luminosity of all known  $z > 4$  AGN (compare with Stern et al. 2000).

We have estimated  $\alpha_{\text{ox}}$ , the slope of a nominal power law between 2500 Å and 2 keV in the rest frame. A  $\Gamma = 2$  power law was adopted for the X-ray continuum (following Reeves & Turner 2000), and an optical power-law slope of  $\alpha_o = -0.79$  (see Schneider, Schmidt, & Gunn 1991 and Fan et al. 2001) was used to calculate the 2500 Å flux density from the AB<sub>1450</sub> magnitude. We find  $\alpha_{\text{ox}} = -1.46$ . This value of  $\alpha_{\text{ox}}$  is in good agreement with  $\alpha_{\text{ox}}$  values found for low-redshift AGN of comparable luminosity (e.g., Brandt, Laor, & Wills 2000, hereafter BLW). There is no evidence that the X-rays are strongly suppressed by internal absorption, although given that we are only sensitive to hard X-rays in the rest frame the intrinsic  $N_{\text{H}}$  is only constrained to be  $\lesssim 5 \times 10^{23}$  cm $^{-2}$ .

In contrast to the results from optically and radio selected AGN surveys, *ROSAT* surveys do not show a significant decrease in the space density of high-redshift, high-luminosity AGN (see §5 of Miyaji, Hasinger, & Schmidt 2000). Our X-ray detection of the moderate-luminosity AGN VLA J123642.09+621331.4 should ultimately be useful for pinning down the X-ray luminosity function (XLF) of AGN when combined with the results from other deep X-ray surveys. At present it is difficult to assess the relation of VLA J123642.09+621331.4 to the XLF because its X-ray luminosity is  $\approx 10$  times lower than those used for all high-redshift XLF studies to date.

*CXOHDFN J123644.3+621132*: This X-ray source is coincident with a Fanaroff-Riley I (FR I) radio galaxy at  $z = 1.050$  that is one of the brightest radio sources in our field (its 1.4 GHz flux density is 1.29 mJy; Richards et al. 1998; Richards 2000). Its radio structure is extended over  $\approx 40''$ , but we only detect the core in X-rays (see Figure 4). The host galaxy is a large elliptical and is a Very Red Object (VRO) with  $\mathcal{R} - K_s = 5.10$  (Hogg et al. 2000).

Using stacking techniques, H01 found evidence for two X-ray emission classes of VROs: (1) X-ray luminous VROs with hard X-ray spectra and (2) lower X-ray luminosity VROs with softer X-ray spectra. CXOHDFN J123644.3+621132 is only detected in the soft band and appears to be a member of the second class that has now been individually detected (previously the X-ray emission from the second class was only detectable when many objects were stacked). Most of the X-ray emission from CXOHDFN J123644.3+621132 is probably associated with the AGN, although

some may arise from the hot interstellar medium of the host galaxy.

FR I sources are often located in clusters of galaxies, but no evidence is found for diffuse X-ray emission around CXOHDFN J123644.3+621132. No hint of X-ray emission from the other  $z \approx 1.050$  objects near CXOHDFN J123644.3+621132 is seen (see §6.1 of Richards et al. 1998).

*CXOHDFN J123648.3+621426*: This source is coincident with a bright  $z = 0.139$  elliptical located at the edge of the HDF-N (see Figure 5). This galaxy has also been detected at radio and mid-infrared wavelengths (Richards et al. 1998; Aussel et al. 1999). The mid-infrared colors from *ISO* are consistent with the re-emission of starlight by interstellar grains as opposed to the light from cool stars (Rowan-Robinson et al. 1997). Given the low X-ray luminosity of this source and its detection in only the soft band, the observed X-ray emission can be plausibly explained by emission from a hot interstellar medium, perhaps combined with emission from X-ray binaries.

*CXOHDFN J123649.5+621345*: This source is located  $\approx 1.33''$  from the center of one of the optically brightest galaxies in the HDF-N, an S0 or elliptical at  $z = 0.089$  (see Figure 5); the corresponding projected physical offset is  $\approx 2.6$  kpc. Although the photon statistics are limited, the fact that this offset is  $\gtrsim 3$  times larger than the offsets for the other sources (see Table 3) argues that the X-ray source is indeed off-nuclear. The 0.5–8.0 keV luminosity of  $\approx 2 \times 10^{39}$  erg s $^{-1}$  is comparable to that of the most luminous X-ray binaries in the Local Group, and an X-ray binary nature for this source would naturally explain its off-nuclear location.

*CXOHDFN J123649.7+621312*: The X-ray source is coincident with the nucleus of an edge-on spiral at  $z = 0.475$  (see Figure 5) that is also a steep-spectrum radio source (Richards et al. 1998). The radio emission is thought to be predominantly due to starburst activity (see Chapter 4 of Richards 1999). The soft-band X-ray luminosity of  $\approx 5 \times 10^{40}$  erg s $^{-1}$  is  $\approx 5$  times that of the prototype starburst galaxy M82 (e.g., Griffiths et al. 2000). This galaxy probably hosts a powerful starburst and/or a low-luminosity active nucleus.

### 3.2. Further Results on Previously Detected Sources

The other eight sources detected in the HDF-N have already been described in H00 and H01; all of these previously reported sources are still detected in our improved analysis here. Below we report on some new results for these sources.

*CXOHDFN J123639.5+621230*: This source is associated with a  $z = 3.479$  broad-line AGN (see H01). The K-S test indicates highly significant count-rate variability in the full band; a constant count rate is rejected with  $> 99.9\%$  confidence (see Table 2). The variability is also apparent in Figure 6. During the first four observations, 15 source plus background counts were obtained in 221.9 ks, while during the last two observations 51 counts were obtained in 257.9 ks. The Poisson probability of obtaining the last two observations (or any with a higher number of counts) given the first four is  $\sim 5 \times 10^{-11}$ ; we therefore consider the variability to be highly significant even

after consideration of issues such as those described by Press & Schechter (1974). We are not aware of any instrumental effects that might explain the observed variability, and we only expect  $\approx 4.0$  background counts in our aperture (see §2) during the entire 479.7 ks exposure. We note that the much brighter source CXOHDFN J123646.3+621404 does not show significant evidence for variability; apparent variability of this source might have been expected if the X-ray detection efficiency had changed substantially between observations.<sup>2</sup> The observed count-rate variability by a factor of  $\approx 3$  occurred over  $\approx 2.7$  months in the object’s rest frame; CXOHDFN J123639.5+621230 is one of the highest redshift X-ray variable objects known.

*CXOHDFN J123643.9+621249:* This *Chandra* source is associated with a  $z = 0.557$  AGN candidate (see H01). The K-S test suggests count-rate variability of this source at the 98.5% confidence level (see Table 2). Examination of the soft-band light curve in Figure 6 indicates a probable drop in count rate during the last two observations. During the first four observations, we obtained seven source plus background counts in 221.9 ks, while during the last two observations we obtained zero counts in 257.9 ks. The Poisson probability of obtaining the last two observations given the first four is  $\sim 3 \times 10^{-4}$ , so the variability is considered to be significant at the  $\approx 3.5\sigma$  level. The required amplitude of count-rate variability is poorly constrained, but we estimate it to be at least a factor of  $\approx 2$ . This apparent X-ray variability supports the AGN nature of this source.

*CXOHDFN J123646.3+621404:* We have now collected sufficient counts from this  $z = 0.960$  broad-line AGN for moderate-quality spectral fitting. In this fitting, we have treated separately the data taken when the focal plane temperature was  $-110^\circ\text{C}$  and  $-120^\circ\text{C}$ ; the spectra and response matrices were created following G01. A simple power-law model with only Galactic absorption clearly fails to fit the spectrum and is statistically rejected with  $> 99.9\%$  confidence. The resulting residuals strongly suggest the presence of intrinsic X-ray absorption (note also the fairly large band ratio of this source; see Table 2); when neutral intrinsic absorption is added we obtain a good fit with  $\chi^2 = 31.9$  for 37 degrees of freedom (see Figure 7). The derived intrinsic column density is  $(3.97^{+1.41}_{-0.94}) \times 10^{22} \text{ cm}^{-2}$  and the photon index is  $\Gamma = 1.57^{+0.26}_{-0.22}$  (fit parameter errors are quoted for  $\Delta\chi^2 = 2.71$  here and hereafter); the photon index, while rather flat, is consistent with those seen from other AGN of comparable luminosity (e.g., Brandt, Mathur, & Elvis 1997). The addition of ionized intrinsic absorption can also provide a good fit to the data, although the fit parameters are poorly constrained.

The large intrinsic column density derived for the X-ray source has prompted us to search for signs of absorption at other wavelengths: e.g., occultation of the Broad Line Region by a torus or absorption in the rest-frame ultraviolet (UV). Phillips et al. (1997) have described a Keck spectrum of this object, and we have obtained and analyzed this spectrum via the DEEP project database.<sup>3</sup> Two narrow Mg II absorption doublets are seen superposed upon the blue

---

<sup>2</sup>See <http://www.astro.psu.edu/users/townsley/cti/I3memo/> for constraints on temporal changes of the X-ray detection efficiency when radiation damage correction is performed with the procedure of Townsley et al. (2000).

<sup>3</sup>See <http://deep.ucolick.org/hdf/hdf.html>

wing of the broad ( $\text{FWHM} \approx 6700 \text{ km s}^{-1}$ ) Mg II emission line (see Figure 8 and Phillips et al. 1997). For the stronger doublet, the rest-frame equivalent widths (EWs) of the Mg II  $\lambda 2796.35$  and Mg II  $\lambda 2803.53$  absorption lines are  $2.7 \pm 0.4 \text{ \AA}$  and  $3.1 \pm 0.4 \text{ \AA}$ , respectively. For the weaker doublet, the corresponding EWs are  $1.4 \pm 0.3 \text{ \AA}$  and  $1.2 \pm 0.4 \text{ \AA}$ . While the breadth of the observed Mg II emission line demonstrates that the Broad Line Region is not hidden by a torus (i.e., this is not a Type 2 AGN), there is clearly absorbing material along the line of sight.

Intrinsic X-ray and UV absorption are often seen together in the spectra of Seyfert galaxies and quasars, although the precise relation between these two forms of absorption is still debated (e.g., Crenshaw et al. 1999; BLW; and references therein). The large column density derived for the X-ray absorber strongly suggests that it is related to the AGN. The UV Mg II absorption is also likely to be intrinsic given the large doublet EWs and the fact that there are two absorption doublets so close together (compare with Steidel & Sargent 1992 and Aldcroft, Bechtold, & Elvis 1994). The EW ratios of the Mg II doublets are consistent with both of them being saturated, and it is not possible to derive reliable Mg II column densities from these data. The outflow velocity for the stronger Mg II doublet is  $\approx 230 \text{ km s}^{-1}$ , and the outflow velocity for the weaker doublet is  $\approx 1700 \text{ km s}^{-1}$ ; these velocities are measured relative to the systemic redshift of  $z = 0.960$  rather than the poorly defined peak of the Mg II emission line (see Phillips et al. 1997). It is possible that both the X-ray and UV absorption arise in an outflowing “warm absorber” similar to those seen in Seyfert galaxies at low redshift.

Although this AGN is known to be optically variable (Sarajedini et al. 2000) and is by far the brightest X-ray source in the HDF-N, no significant X-ray variability is detected.

*CXO HDFN J123651.7+621221*: This source is coincident with the remarkably red object NICMOS J123651.74+621221.4 (Dickinson et al. 2000) which has been argued to be either a high-redshift starburst enshrouded in dust (e.g., Muxlow et al. 1999) or a Type 2 quasar candidate (H00). With the increased exposure time, this source is now detected in the ultrahard band from 4–8 keV with  $9.73 \pm 3.32$  counts. If this source is indeed at moderate or high redshift (see Table 3), it almost certainly contains an active nucleus given its large hard X-ray luminosity and its hard X-ray spectral shape. Note that it has the largest band ratio of any source in the HDF-N (see Table 2).

Although this object is the second brightest X-ray source in the HDF-N and is of great scientific interest, only crude X-ray spectral fitting is possible at present. The large band ratio suggests the probable presence of X-ray absorption, so we have fitted the spectrum with a  $\Gamma = 2$  power-law model that is absorbed by neutral gas at  $z = 2.7$  (see Table 3). The resulting fit is acceptable although poorly constrained, and the best-fit column density is  $(4.27^{+2.27}_{-1.72}) \times 10^{23} \text{ cm}^{-2}$ . The corresponding absorption-corrected luminosity in the 0.5–8.0 keV band is  $\approx 2 \times 10^{44} \text{ erg s}^{-1}$ .

### 3.3. Band Ratios

In Figure 9 we show a plot of X-ray band ratio, defined as the ratio of hard-band to soft-band counts, versus soft-band count rate. This compares the HDF-N sources detected here to the sources detected with 221.9 ks of *Chandra* exposure by H01 (also compare with Figure 2 of Giacconi et al. 2001). Our faintest HDF-N sources occupy a region of low count rate and relatively low band ratio that has not been previously seen for individual sources, although stacking analyses had suggested that sources would occupy this region (see Giacconi et al. 2001 and H01). This is partially due to the fact that, with more exposure, we can place tighter upper limits on the X-ray band ratios for several of these sources.

The two hardest X-ray sources in the HDF-N itself are CXOHDFN J123646.3+621404 and CXOHDFN J123651.7+621221; notably, these are also the two brightest HDF-N sources in terms of their full-band emission (see Table 2). In §3.2 it was shown that the hard spectrum of CXOHDFN J123646.3+621404 is almost certainly due to intrinsic X-ray absorption, and this is probably the case for CXOHDFN J123651.7+621221 as well.

### 3.4. Stacking Analysis Results

#### 3.4.1. Optically Bright Galaxies

Several of the optically bright galaxies in the HDF-N have now been found to be low-luminosity X-ray sources (see Figure 2). In order to extend these results, a stacking analysis was performed to attempt to detect the HDF-N galaxies from W96 with  $V_{606} < 22.5$  that are not individually detected in X-rays. Two  $V_{606} < 22.5$  galaxies lying near (but unrelated to) relatively bright *Chandra* sources were removed from consideration to minimize background and avoid any contamination (sources 3-400.0 and 3-659.0 in W96). The X-ray data for all  $V_{606} < 22.5$  galaxies were manually inspected to ensure that none of them is an X-ray source lying just below the detection limit; none contains a point source with  $\gtrsim 5$  detected full-band counts. The resulting galaxy sample has 17 objects with  $V_{606}$  from 19.9–22.5 including 11 spirals, three ellipticals and three irregulars (see Table 4 and Figure 2). None of these galaxies is known to have broad optical emission lines (Cohen et al. 2000), and none of them has been identified as an AGN candidate in the searches of Jarvis & MacAlpine (1998), Conti et al. (1999), Liu et al. (1999), Sarajedini et al. (2000) and Vanden Berk et al. (2000). Only two of them (sources 2-404.0 and 2-736.0 in W96) have been detected in the radio by Richards et al. (1998) and Richards (2000). The effective exposure time of the stacked image is 7.7 Ms, and we have used the restricted ACIS grade set in this analysis.

If the galaxies under study are indeed X-ray sources, some of them are likely to have their X-ray emission offset from their nuclei (as for the cases of CXOHDFN J123641.7+621131 and CXOHDFN J123649.5+621345), but without a priori knowledge of the location of this emission we are limited to stacking these galaxies at their nuclei (with one exception; see Table 4). Given the

optical extents of these galaxies, X-ray emission up to  $\approx 1.5''$  from the nucleus is plausible in most cases. Therefore, for each galaxy the 30 pixels with centers within  $1.5''$  of the stacking position were considered. In the full-band stacked image, 79 counts were detected in these 30 pixels while 49.7 are expected from background. The Poisson probability of obtaining 79 counts or more when 49.7 are expected is only  $8 \times 10^{-5}$ , so full-band X-ray emission from the average galaxy is detected with high significance. Figure 10 shows that the full-band X-ray emission appears to be well centered on the nuclear positions of the galaxies, although the centroid position is in fact uncertain at the  $\approx 1''$  level due to the combination of limited photon statistics, background, and the ACIS pixel size. There also appears to be a detection in the stacked soft-band image. Following the same procedure as for the full-band image, we obtain 29 events when 10.5 are expected; the corresponding Poisson probability is  $2 \times 10^{-6}$ . The soft-band emission centroid appears somewhat offset from the nuclear positions (see Figure 10), although as above we note that the centroid position is fairly uncertain. We have not found statistically significant evidence for a detection in the hard-band stacked image.

Source searching with WAVDETECT confirms the detections from the manual Poisson calculations above, although the detection significances are somewhat lower. The full-band and soft-band sources are detected when WAVDETECT is run with probability thresholds of  $5 \times 10^{-5}$  and  $2 \times 10^{-5}$ , respectively. Given that 30 pixels are being searched in each case, the respective probabilities of false detections are  $\approx 1.5 \times 10^{-3}$  and  $\approx 6 \times 10^{-4}$ . Monte-Carlo simulations were also performed to examine the reliability of the stacking analyses; good agreement was obtained with the Poisson statistics calculations above (see Appendix A). Finally, we comment that the stacking analyses are not subject to biases such as those discussed by Eddington (1913) because the number of sources under consideration is fixed and was not determined using the X-ray data.

One concern with the interpretation of an average brightness from a stacking analysis is that simply dividing the observed number of counts by the number of sources does not necessarily yield an accurate estimate of the characteristic brightness of the population; e.g., the bulk of the observed counts might be produced by only one or two sources. In this study, however, we believe that averages do reasonably reflect typical brightnesses. In the full-band stacking above, for example, there are  $\approx 29.3$  observed counts from 17 sources. No individual source, as noted above, has  $\gtrsim 5$  counts. Therefore at least  $\approx 6$  sources, and very likely more, are contributing to the observed counts.

We have repeated the stacking analysis above for only the 11 spirals with  $V_{606} < 22.5$  (see Table 4); the effective exposure time of the resulting stacked image is 5.0 Ms. In the full-band image we obtain 47 events when 32.1 are expected (see Figure 10); the corresponding Poisson probability is  $8 \times 10^{-3}$ , and the Monte-Carlo analysis in Appendix A gives essentially the same probability. This detection is significant at the 99.2% confidence level. We do not obtain significant detections in the soft band or hard band.

### 3.4.2. Radio Sources

In H00 we described the fairly good correspondence between X-ray sources and radio sources, and this continues now that deeper X-ray data are available. For example, eight of our 12 *Chandra* sources in the HDF-N are detected at 8.5 GHz by Richards et al. (1998). Furthermore, we preferentially detect in X-rays the brighter 8.5 GHz sources: all but one of the six radio sources with 8.5 GHz fluxes above  $10\ \mu\text{Jy}$  are detected, compared to only three of the nine radio sources with 8.5 GHz fluxes below  $10\ \mu\text{Jy}$ . To constrain the X-ray properties of the seven 8.5 GHz HDF-N sources not detected individually in X-rays, we have stacked them but do not obtain statistically significant point-source detections in any of our bands. Our upper limit on a point source in the full-band stacked image is  $\approx 6.8$  counts in 3.2 Ms (this is a 95% confidence upper limit calculated following Kraft, Burrows, & Nousek 1991). Adopting the spectral model used in §2.2, the upper limit on the full-band flux of the average source is  $\approx 2.1 \times 10^{-17}\ \text{erg cm}^{-2}\ \text{s}^{-1}$ .

## 4. Discussion

### 4.1. General Source Properties and Number Counts

With the new data, the number of *Chandra* sources detected in the HDF-N itself has risen from eight (H01) to 12. Nine of these 12 sources are detected in the full band, 11 are detected in the soft band, six are detected in the hard band, and two are detected in the ultrahard band. We have not found any sources that are detected only in the hard or ultrahard bands. All of the *Chandra* HDF-N sources have likely counterparts at optical or near-infrared wavelengths.

The corresponding soft-band and hard-band source densities for this  $5.3\ \text{arcmin}^2$  field are  $7500 \pm 3000\ \text{deg}^{-2}$  (at  $4.9 \times 10^{-17}\ \text{erg cm}^{-2}\ \text{s}^{-1}$ ) and  $4100 \pm 2400\ \text{deg}^{-2}$  (at  $2.3 \times 10^{-16}\ \text{erg cm}^{-2}\ \text{s}^{-1}$ ), respectively (error bars on these values have been calculated following Gehrels 1996). These flux limits are a factor of  $\approx 2$  lower than those previously reported (G01; Giacconi et al. 2001; Hasinger et al. 2001), and these source densities are the highest yet reported. The number counts in the soft band lie somewhat above an extrapolation of those in G01, although the discrepancy is not highly significant; any excess may be due to the emergence of the optically bright galaxies as low-luminosity X-ray sources (see §5.4 of H01). The number counts in the hard band are consistent with an extrapolation of those in G01.

### 4.2. Stacking Analyses of Optically Bright Galaxies

A comparison of our HDF-N X-ray source list with the Cohen et al. (2000) and Cohen (2001) redshift catalogs for the HDF-N reveals that we have now detected three of the five lowest-redshift ( $z < 0.15$ ) galaxies known in the HDF-N including all of those with  $M_V < -18$  (the two non-detected galaxies at  $z < 0.15$  both have absolute magnitudes of only  $M_V \approx -15$ ). This high

detection fraction is understandable given that we have now achieved the sensitivity needed to detect the most luminous ( $\gtrsim 2 \times 10^{39}$  erg s $^{-1}$ ) X-ray binaries and supernova remnants at  $z \lesssim 0.15$  (e.g., Schlegel 1995; Makishima et al. 2000). Indeed, two of our three low-redshift X-ray detections are spatially offset from their host galaxies’ nuclei. For comparison, our sensitivity limit would allow us to detect the Galactic microquasar GRS 1915+105 (one of the most luminous X-ray sources in the Galaxy; e.g., Greiner, Morgan, & Remillard 1996) to  $z \approx 0.1$ . Similarly, we could detect the most luminous known off-nuclear source in M82 at its peak (e.g., Kaaret et al. 2001) to  $z \approx 0.5$ .

The stacking analyses in §3.4.1 have extended our constraints on galaxy X-ray emission to  $z \approx 0.2$ –1 for galaxies with  $V_{606} = 19.9$ –22.5. These analyses are complementary to the cross-correlation work performed with *ROSAT* on galaxies with similar optical magnitudes (e.g., Almaini et al. 1997 and references therein; also see Refregier, Helfand, & McMahon 1997 for the cross-correlation work on optically brighter galaxies). Because of our much greater sensitivity, we are able to obtain a positive signal with many fewer galaxies (the *ROSAT* cross-correlations needed  $\sim 5000$  galaxies while we used 11–17). The greater sensitivity of this study also provides much tighter constraints on the X-ray luminosities of the individual galaxies used in the analysis. For comparison, the 0.5–2.0 keV luminosity limit for an individual galaxy at  $z = 0.7$  is  $\approx 9 \times 10^{40}$  erg s $^{-1}$  in the current study while the *ROSAT* cross-correlation studies had individual galaxy luminosity limits of  $\approx 8 \times 10^{42}$  erg s $^{-1}$  at this redshift. Unlike the *ROSAT* cross-correlation studies, we should be fairly immune to contamination by Seyfert nuclei (e.g., see §4 of Almaini et al. 1997); note that our good 2–8 keV sensitivity should also allow us to avoid moderately obscured AGN with low-level soft X-ray emission. It is still possible that some low-luminosity AGN remain in the galaxy sample in Table 4; low-luminosity AGN are seen in  $\sim 40\%$  of local galaxies and have X-ray luminosities ranging from  $\lesssim 10^{38}$  erg s $^{-1}$  to  $10^{41}$  erg s $^{-1}$  with a median luminosity of  $\sim 4 \times 10^{38}$  erg s $^{-1}$  (e.g., Ho et al. 2001). None of the galaxies in Table 4 has been identified as an AGN in the intensive HDF-N follow-up studies (see §3.4.1), although the current optical spectroscopy probably would not have detected the subtle spectral features often associated with low-luminosity AGNs.

Stacking the full-band images of the 11 spirals in Table 4 results in a detection of  $\approx 14.9$  net counts in an effective exposure time of 5.0 Ms. At the median redshift of  $z = 0.474$ , the rest-frame bandpass corresponding to the full-band detection is 0.74–11.79 keV. Provided the basic X-ray production mechanisms in these spirals are similar to those of spirals in the local Universe, the emission in this bandpass is probably dominated by X-ray binaries and has an effective power-law photon index of  $\Gamma \approx 2.0$  (e.g., Kim, Fabbiano, & Trinchieri 1992). With this spectral model and the Galactic column density, the observed count rate implies a 0.5–8.0 keV flux of  $\approx 2.3 \times 10^{-17}$  erg cm $^{-2}$  s $^{-1}$  for the average spiral in our sample (the corresponding 0.5–2.0 keV flux is  $\approx 1.1 \times 10^{-17}$  erg cm $^{-2}$  s $^{-1}$ ).<sup>4</sup> At the median redshift of  $z = 0.474$ , the implied rest-frame 0.5–8.0 keV luminosity is  $\approx 1.6 \times 10^{40}$  erg s $^{-1}$ .

---

<sup>4</sup>We have corrected for the use of the restricted ACIS grade set rather than the standard *ASCA* grade set using the count ratios determined for CXOHDFN J123646.3+621404 in §2.1.

Normal spirals in the local Universe ( $z < 0.01$ ) with optical luminosities similar to those in the stacking sample have X-ray luminosities in the range  $\approx 2 \times 10^{39} \text{ erg s}^{-1}$  to  $\approx 1 \times 10^{40} \text{ erg s}^{-1}$  (e.g., the  $M_B < -18$  spirals in Fabbiano, Trinchieri, & MacDonald 1984).<sup>5</sup> Our derived luminosity of  $\approx 1.6 \times 10^{40} \text{ erg s}^{-1}$  for the average  $z \approx 0.5$  spiral is thus somewhat higher than those observed for normal  $z < 0.01$  spirals. However, this average luminosity is not highly inconsistent given the uncertainties and the possible presence of low-luminosity AGN in some of our spirals. At the median redshift of  $z = 0.474$ , the lookback time is  $\approx \frac{1}{3}$  of the Hubble time. Thus, if our sample is representative of the Universe as a whole, it appears that the X-ray luminosities of normal spirals have not evolved upward by more than a factor of  $\approx 3$  over the past  $\approx 4.5 \text{ Gyr}$ .

White & Ghosh (1998) considered the effects of the declining cosmic star-formation rate on the evolution of low-mass X-ray binary (LMXB) populations in galaxies. They suggested that LMXB activity should peak at  $z \approx 0.5$ –1 (rather than coincident with the peak in the cosmic star-formation rate) because the evolutionary timescale for LMXBs is a non-negligible fraction of the Hubble time. They also estimated that the X-ray luminosities of  $z \approx 0.5$ –1 galaxies should be at least an order of magnitude higher than they are today. While our current data suggest that the average galaxy X-ray luminosity at  $z \approx 0.5$  may be up to a factor of  $\approx 3$  higher than at  $z < 0.01$ , we do not see any evidence for an order-of-magnitude luminosity increase at this redshift. These are the first significant constraints on models such as those proposed by White & Ghosh (1998).

### 4.3. Narrow Emission-Line Galaxies

Our new data also allow us to test some predictions made previously about X-ray sources in the HDF-N. Almaini & Fabian (1997), for example, made predictions of the number of AGN in the HDF-N and proposed that X-ray luminous narrow-emission line galaxies (NELGs) may comprise up to  $\approx 10\%$  of the  $\approx 3000$  galaxies in the HDF-N. At our current soft-band sensitivity level, they predict  $\approx 9$  NELGs to be present. Six of the 12 HDF-N sources in Table 3 have some narrow emission lines in their optical spectra (we exclude broad-line AGN and objects with absorption-dominated spectra). Two of these (CXOHDFN J123641.7+621131 and CXOHDFN J123648.3+621426), however, have X-ray luminosities below those typically associated with the NELG population (their X-ray to optical flux ratios are more representative of those of normal galaxies). Thus, we presently detect at most four X-ray luminous NELGs in the HDF-N (CXOHDFN J123643.99+621249.8, CXOHDFN J123648.0+621309, CXOHDFN J123649.7+621312 and CXOHDFN J123656.9+621301), below the predictions of Almaini & Fabian (1997). Higher quality optical spectroscopy of these four objects may well reveal that some of them contain previously unrecognized AGN.

---

<sup>5</sup>We have corrected the luminosities from Fabbiano et al. (1984) for bandpass effects and have converted them into our adopted cosmology.

## 5. Summary

We have used a 479.7 ks *Chandra* image, the deepest X-ray observation ever presented, to study the X-ray source content of the HDF-N and its immediate vicinity. The key results are the following:

- Four new X-ray sources in the HDF-N itself have been discovered bringing the total number of HDF-N X-ray sources to 12. Two of the new sources are optically bright galaxies at low redshift; with their detection we have now detected X-ray emission from all three of the optically luminous ( $M_V < -18$ ) HDF-N galaxies with  $z < 0.15$ . The other two new X-ray sources are an FR I radio galaxy and an edge-on spiral that hosts a powerful starburst and/or low-luminosity AGN. See §3.1 and §4.1.
- The remarkable  $\mu\text{Jy}$  radio source VLA J123642.09+621331.4 is detected by *Chandra*. This source has a likely redshift of  $z = 4.424$ , and this X-ray detection supports the presence of an AGN in this object. The  $\alpha_{\text{ox}}$  value of VLA J123642.09+621331.4 is in good agreement with  $\alpha_{\text{ox}}$  values found for low-redshift AGN. See §3.1.
- X-ray variability is found from the  $z = 3.479$  broad-line AGN CXOHDFN J123639.5+621230 and the  $z = 0.557$  AGN candidate CXOHDFN J123643.9+621249. The first brightens by a factor of  $\approx 3$  over  $\approx 2.7$  months in the rest frame, while the second dims by a factor of  $\gtrsim 2$  in a rest-frame time interval of  $\approx 8$  months. The X-ray variability of CXOHDFN J123643.9+621249 strongly supports the presence of an AGN. See §3.2.
- We have modeled the X-ray spectrum of the brightest X-ray source in the HDF-N, the  $z = 0.960$  broad-line AGN CXOHDFN J123646.3+621404. We find evidence for intrinsic X-ray absorption with a column density of  $\approx 4 \times 10^{22} \text{ cm}^{-2}$ . This absorption is plausibly related to the Mg II absorption doublets that are superposed upon the blue wing of the broad Mg II emission line. See §3.2.
- Stacking analyses of  $V_{606} < 22.5$  galaxies not individually detected in X-rays have provided estimates of the average X-ray fluxes of these objects. Their X-ray emission probably arises from combinations of X-ray binaries, supernova remnants, and low-luminosity AGN. The average X-ray luminosity of normal spiral galaxies at  $z \approx 0.5$  appears similar to, although perhaps slightly higher than, that of spirals in the local Universe; this constrains models for the evolution of LMXB populations in galaxies in response to the declining cosmic star-formation rate. Monte-Carlo simulations demonstrate the validity of the stacking analyses and show that the *Chandra* ACIS performs well at source detection even with effective exposure times of  $\approx 8$  Ms. See §3.4, §4.2 and Appendix A.
- We have constrained the size of the population of X-ray luminous NELGs at the faintest X-ray fluxes. These sources are less common than has been predicted. See §4.3.

This work would not have been possible without the enormous efforts of the entire *Chandra* and ACIS teams. We thank A.J. Barger, J.C. Charlton, C.W. Churchill and L.L. Cowie for helpful discussions. We gratefully acknowledge the financial support of NASA grant NAS 8-38252 (GPG, PI), NSF CAREER award AST-9983783 (WNB, DMA), NASA GSRP grant NGT5-50247 and the Pennsylvania Space Grant Consortium (AEH), and NSF grant AST99-00703 (DPS).

### A. Monte-Carlo Testing of the Stacking Analyses

The stacking methods employed in §3.4.1 have allowed us to study the properties of full-band sources down to flux levels of  $\approx 2.3 \times 10^{-17}$  erg cm $^{-2}$  s $^{-1}$ , pushing the source detection ability of *Chandra* beyond what has been achieved previously. As such, one must be cautious of instrumental effects and other potential problems that could lead to false source detections in the stacked images. In order to perform an “end-to-end” test of the stacking analysis and empirically assess false-detection probabilities, we have performed Monte-Carlo simulations. These were designed to reproduce the actual stacking performed as closely as possible.

Consider the full-band stacking analysis of the 17 galaxies in Table 4 performed in §3.4.1. To test this analysis, we have randomly selected 17 positions chosen to be at least 8 pixels from known sources and to have similar background levels to those of the actual galaxies being stacked. We have then constructed a stacked image from the data around these 17 positions and determined the number of counts in the 30 pixels with centers within 1.5'' of the stacking position (just as was done at the actual galaxy positions; see §3.4.1). Repeating the above 100,000 times, we have determined a distribution function showing the number of random trials giving a particular number of counts. The result is shown in Figure 11a. The resulting distribution is closely Gaussian; a Gaussian fit gives a mean of 49.1 counts and a standard deviation of  $\sigma = 7.0$  counts. At the actual galaxy positions we obtained 79 counts. Only 9 of the 100,000 random trials yielded 79 counts or more, so the false-detection probability is only  $\approx 9 \times 10^{-5}$ . For comparison, the Poisson statistics calculation in §3.4.1 gave a false detection probability of  $8 \times 10^{-5}$ . The good agreement between the Monte-Carlo and Poisson statistics calculations gives us further confidence in the reliability of our stacking analyses and argues that there are no subtle instrumental effects causing false source detections. For example, subtle cosmic ray afterglows in ACIS could not cause a false detection since they will not be preferentially aligned with optically bright HDF-N galaxies. The ACIS performs well at source detection even with effective exposure times of  $\approx 8$  Ms.

We have also performed Monte-Carlo testing of the other analyses presented in §3.4.1. The results are shown in Figures 11b and 11c, and we consistently obtain good agreement with the results presented in §3.4.1.

<sup>a</sup>Bands in which this source is detected. “F” indicates full band, “S” indicates soft band, “H” indicates hard band. With two exceptions, detections are at the  $1 \times 10^{-7}$  false-positive probability level using either the standard ACIS grade set. The first exception is the full-band detection of CXOHDFN J123649.7+621312 which is at the standard *ASCA* grade set and the restricted ACIS grade set. The second exception is the full-band detection which is at the  $1 \times 10^{-5}$  probability level for the restricted ACIS grade set. Because both of these exceptions are level in the soft band, we are confident of their reality (see §2).

<sup>b</sup>Source counts and errors are as computed by WAVDETECT, and these have been verified using manual photometry using the Bayesian method of Kraft, Burrows, & Nousek (1991) for 95% confidence; the uniform prior used conservative upper limits, and other reasonable choices of priors do not materially change our scientific results. *ASCA* grade set, and we have not corrected these values for vignetting. “FB” indicates full band, “SB” indicates soft band, “HB” indicates hard band.

<sup>c</sup>Defined as the ratio of counts between the 2–8 keV and 0.5–2.0 keV bands. Errors for this quantity are computed using the method described in §1.7.3 of Lyons (1991). These values have been corrected for vignetting.

<sup>d</sup>Fluxes are in units of  $10^{-15}$  erg cm<sup>-2</sup> s<sup>-1</sup>. They have been computed using the method detailed in §3.3 of Hubble et al. (2002) for vignetting but are not corrected for Galactic absorption. “FB” indicates full band, “SB” indicates soft band, “HB” indicates hard band.

<sup>e</sup>The probability, as derived from a Kolmogorov-Smirnov test, that the source count rate is consistent with the background level done in the band where a source has its highest signal-to-noise ratio.

<sup>f</sup>This source is located just outside the HDF-N.

Table 3. Identifications of HDF-N *Chandra* Sources

Coordinates		W96	CXO/W96				log( $L_X$ )		Other

<sup>a</sup>Offset between the *Chandra* source and the proposed W96 identification. For CXOHDFN J123651.7+621221.4, and for CXOHDFN J123642.0+621331 we quote the offset from VLA J123642.09+621331.4.

<sup>b</sup>These are Kron-Cousins  $R$  magnitudes (see Bessel 1990) calculated following §4.2 of H01.

<sup>c</sup>Redshifts are from Cohen et al. (2000) and Cohen (2001) unless noted otherwise.

<sup>d</sup>Luminosities are given in the rest frame. “FB” indicates full band, “SB” indicates soft band, and “HB” indicates hard band.

<sup>e</sup>Other wavelength bands in which these sources are detected. R: Radio (Richards et al. 1998; Richards 2000; Alexander et al., in preparation; and references therein).

<sup>f</sup>Optical spectral type from §2.6 of Cohen et al. (2000). “ $\mathcal{E}$ ” galaxies have spectra dominated by emission lines, “ $\mathcal{I}$ ” galaxies have spectra of intermediate type between “ $\mathcal{E}$ ” and “ $\mathcal{A}$ ”, and “ $\mathcal{Q}$ ” galaxies have spectra dominated by absorption lines. See Cohen et al. (2000) for details and explanations of the other spectral types.

<sup>g</sup>The offset between the X-ray source and the spatially coincident off-nuclear “bright spot” is 0.14". The short optical wavelengths, and it may be an off-nuclear starburst region (H00) or background AGN.

<sup>h</sup>The X-ray source is coincident with one of the optically brightest galaxies in the HDF-N, but it is offset from the optical emission from an X-ray binary (see §3.1).

<sup>i</sup>The redshift for CXOHDFN J123651.7+621221 is photometric and subject to significant uncertainty (M. L. 2000).

<sup>j</sup>This redshift has been disputed by Fernández-Soto et al. (2001) who propose  $z = 1.27$ .

<sup>k</sup>This source is located just outside the HDF-N.

<sup>l</sup>See §3.1 and references therein for a discussion of the redshift of this source.

Table 4. Optically Bright HDF-N Galaxies Used in the Stacking Analyses

Name <sup>a</sup>	$\alpha_{2000}^a$	$\delta_{2000}^a$	$V_{606}^a$	$z^b$	Morph. Type <sup>c</sup>	Spect. Type <sup>d</sup>
1-34.0	12 36 44.57	62 13 04.6	22.11	0.485	Spiral	$\mathcal{I}$
1-87.0	12 36 45.85	62 13 25.8	21.49	0.321	Spiral	$\mathcal{I}$

4-656.0	12 36 42.91	62 12 16.2	21.27	0.454	Spiral	$\mathcal{I}$
4-744.0	12 36 43.80	62 11 42.8	22.40	0.765	Elliptical	$\mathcal{A}$
4-795.0	12 36 41.94	62 12 05.4	21.52	0.432	Spiral	$\mathcal{I}$

<sup>a</sup>From W96.

<sup>b</sup>Redshifts are from Cohen et al. (2000) and Cohen (2001).

<sup>c</sup>Morphological classifications are from van den Bergh et al. (1996), Franceschini et al. (1998), Abraham et al. (1999a), and Abraham et al. (1999b).

<sup>d</sup>Optical spectral type from §2.6 of Cohen et al. (2000). “ $\mathcal{E}$ ” galaxies have spectra dominated by emission lines, “ $\mathcal{A}$ ” galaxies have spectra dominated by absorption lines, and “ $\mathcal{I}$ ” galaxies have spectra of intermediate type between “ $\mathcal{E}$ ” and “ $\mathcal{A}$ ”. None of these galaxies is known to have broad optical emission lines. See Cohen et al. (2000) for details and explanations of the other spectral types.

<sup>e</sup>This face-on spiral has a set of bright spots along its arms that are brighter than its nucleus in the rest-frame UV. These are presumably star-forming regions, and we have centered the relevant *Chandra* image on the centroid of these.

Fig. 1.— Adaptively smoothed *Chandra* images of the HDF-N and its immediate environs in the (a) full band, (b) soft band, and (c) hard band. Sources discussed in this paper are labeled; labels are given immediately to the left of the corresponding X-ray sources. Redshifts for these sources are given immediately above the corresponding X-ray sources. These images have been made using the restricted ACIS grade set, and the adaptive smoothing has been performed using the code of Ebeling, White, & Rangarajan (2001) at the  $2.5\sigma$  level. The grayscales are linear.

**This figure is very large and is available from  
<http://www.astro.psu.edu/users/niel/hdf/hdf-chandra.html>**

Fig. 2.— *Chandra* sources detected in the HDF-N circled on the W96 optical image. Sources are labeled by their right ascensions. Green dots are placed above 15 of the 17 optically bright galaxies used in our stacking analysis (we could not mark two of the optically bright galaxies near CXOHDFN J123643.9+621249 and CXOHDFN J123649.7+621312 due to symbol crowding).

Fig. 3.—  $AB_{1450}$  magnitude versus observed-frame, Galactic absorption-corrected 0.5–2.0 keV flux for AGN at  $z > 4$  (adapted from Kaspi et al. 2000 and Brandt et al. 2001). The solid dots are X-ray detected radio-quiet AGN, the stars are X-ray detected radio-loud blazars, and the arrows are X-ray upper limits. The oblique dotted line shows the  $\alpha_{\text{ox}} = -1.50$  locus for  $z = 4.424$  (assuming an optical continuum slope of  $\alpha_o = -0.79$  and an X-ray power-law photon index of  $\Gamma = 2$ ). We have labeled VLA J123642.09+621331.4; provided its likely redshift of  $z = 4.424$  is correct, it is both the X-ray faintest and optically faintest  $z > 4$  AGN detected in X-rays. Despite its faintness, its value of  $\alpha_{\text{ox}}$  is similar to that of much brighter AGN. We have also labeled the notable  $z > 4$  AGN RX J1052+5719 ( $z = 4.45$ ; Schneider et al. 1998) and SDSS 1044-0125 ( $z = 5.80$ ; Fan et al. 2000; Brandt et al. 2001).

Fig. 4.— Image of the FR I AGN VLA J123644.38+621133.0 at 1.4 GHz (Richards 2000) with *Chandra* soft-band contours overlaid. The contours are at 16, 32 and 64% of the maximum pixel value. The X-ray contours near the right-hand edge of the figure correspond to CXO-HDFN J123641.7+621131.

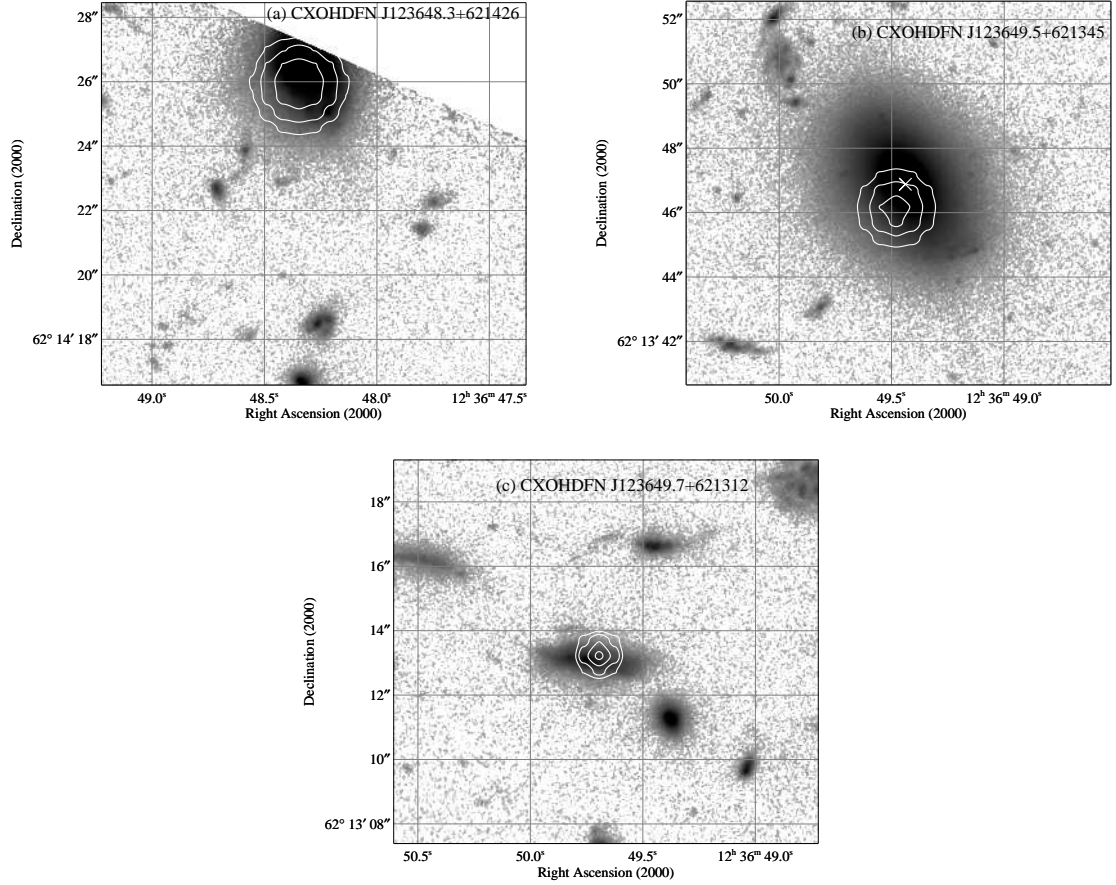

Fig. 5.—  $V_{606}$  images from *HST* with *Chandra* contours for (a) CXOHDFN J123648.3+621426, (b) CXOHDFN J123649.5+621345, and (c) CXOHDFN J123649.7+621312 overlaid. Full-band contours are shown for CXOHDFN J123649.5+621345; soft-band contours are shown for the other two sources. CXOHDFN J123648.3+621426 lies near the edge of the HDF-N image. Note that the X-ray centroid for CXOHDFN J123649.5+621345 is offset from the nucleus of the bright elliptical (marked with a cross).

Fig. 6.— *Chandra* light curves for CXOHDFN J123639.5+621230 and CXOHDFN 123643.9+621249 in the full band and soft band, respectively. The mean count rate is shown for each of the six observations comprising the *Chandra* data set; the first four observations are those listed in Table 1 of H01, and the last two are those described in §2. The exposure times vary substantially from observation to observation, and the time gaps between the observations vary. Error bars have been calculated following Gehrels (1986).

Fig. 7.— *Chandra* ACIS-I observed-frame spectra of CXOHDFN J123646.3+621404 along with the best-fitting absorbed power-law model; the best-fitting power-law photon index is  $\Gamma = 1.57^{+0.26}_{-0.22}$ , and the intrinsic column density is  $(3.97^{+1.41}_{-0.94}) \times 10^{22} \text{ cm}^{-2}$ . The solid dots show the data taken when the focal plane temperature was  $-110^\circ \text{ C}$ , and the plain crosses show the data taken when the focal plane temperature was  $-120^\circ \text{ C}$ . The ordinate for the lower panel, labeled  $\chi$ , shows the fit residuals in terms of standard deviation with error bars of size one.

Fig. 8.— Keck Low-Resolution Imaging Spectrograph (LRIS; Oke et al. 1995) spectrum of the  $z = 0.960$  AGN associated with CXOHDFN J123646.3+621404. The spectral resolution is  $\approx 3 \text{ \AA}$ . This spectrum was taken by the DEEP collaboration (see Phillips et al. 1997), and only the region near the Mg II emission line is shown. Note the two blueshifted Mg II absorption doublets superimposed upon the broad Mg II emission line.

Fig. 9.— Band ratio as a function of soft-band (0.5–2.0 keV) count rate for *Chandra* sources. Plotted are the 479.7 ks *Chandra* sources in Table 2 (stars) as well as the other sources studied by H01 with 221.9 ks (solid dots and plain arrows for limits). Dotted lines are labeled with the photon indices which correspond to a given band ratio (assuming only Galactic absorption). Note that the faintest HDF-N sources occupy a region at low count rate and relatively low band ratio that has not, until now, been seen for individual sources. We were not able to plot CXOHDFN J123649.5+621345 because it is only detected in the full band.

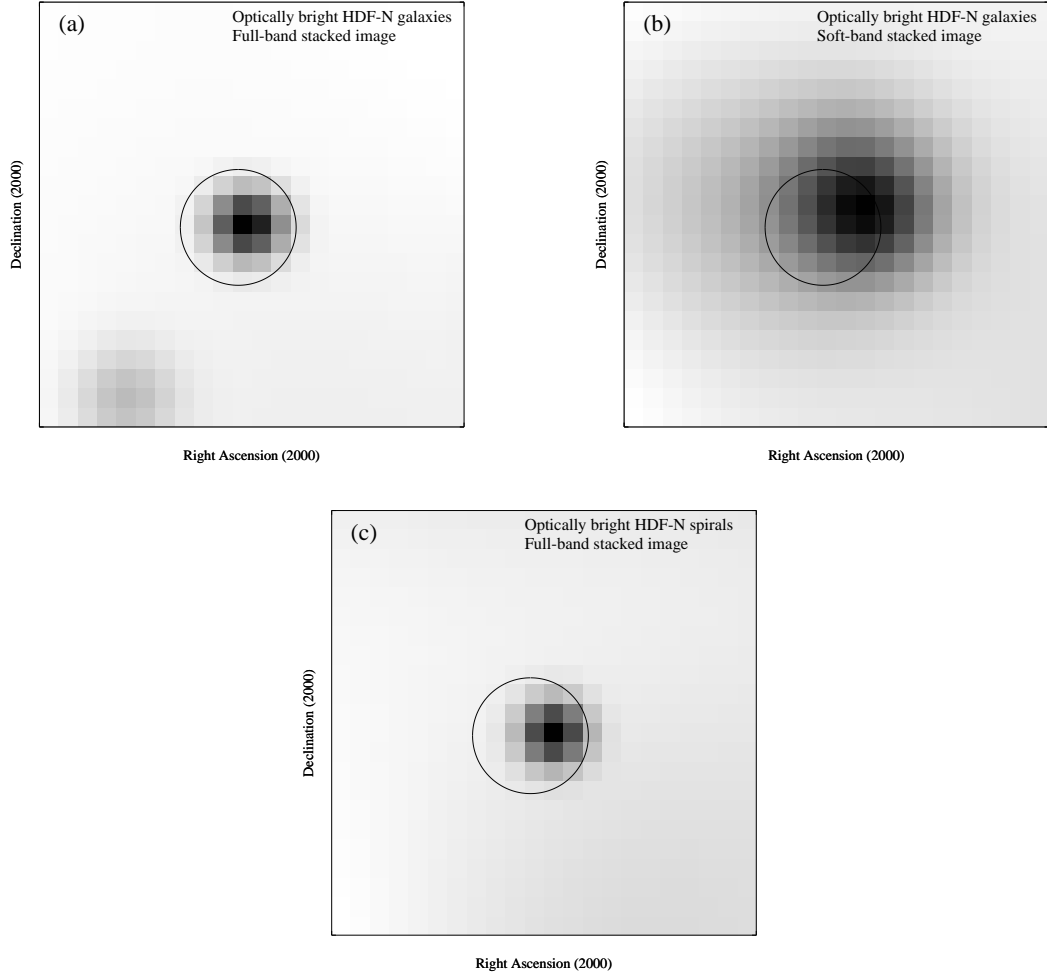

Fig. 10.— Stacked *Chandra* images of (a) optically bright HDF-N galaxies in the full band, (b) optically bright HDF-N galaxies in the soft band, and (c) optically bright HDF-N spirals in the full band. These images have been made using the restricted ACIS grade set, and they have been adaptively smoothed at the  $2.5\sigma$  level using the code of Ebeling et al. (2001). The images are  $11'' \times 11''$  in size, and each pixel is  $0.5''$  on a side. The circle at the center of each image is centered on the stacking position and has a radius of  $1.5''$ .

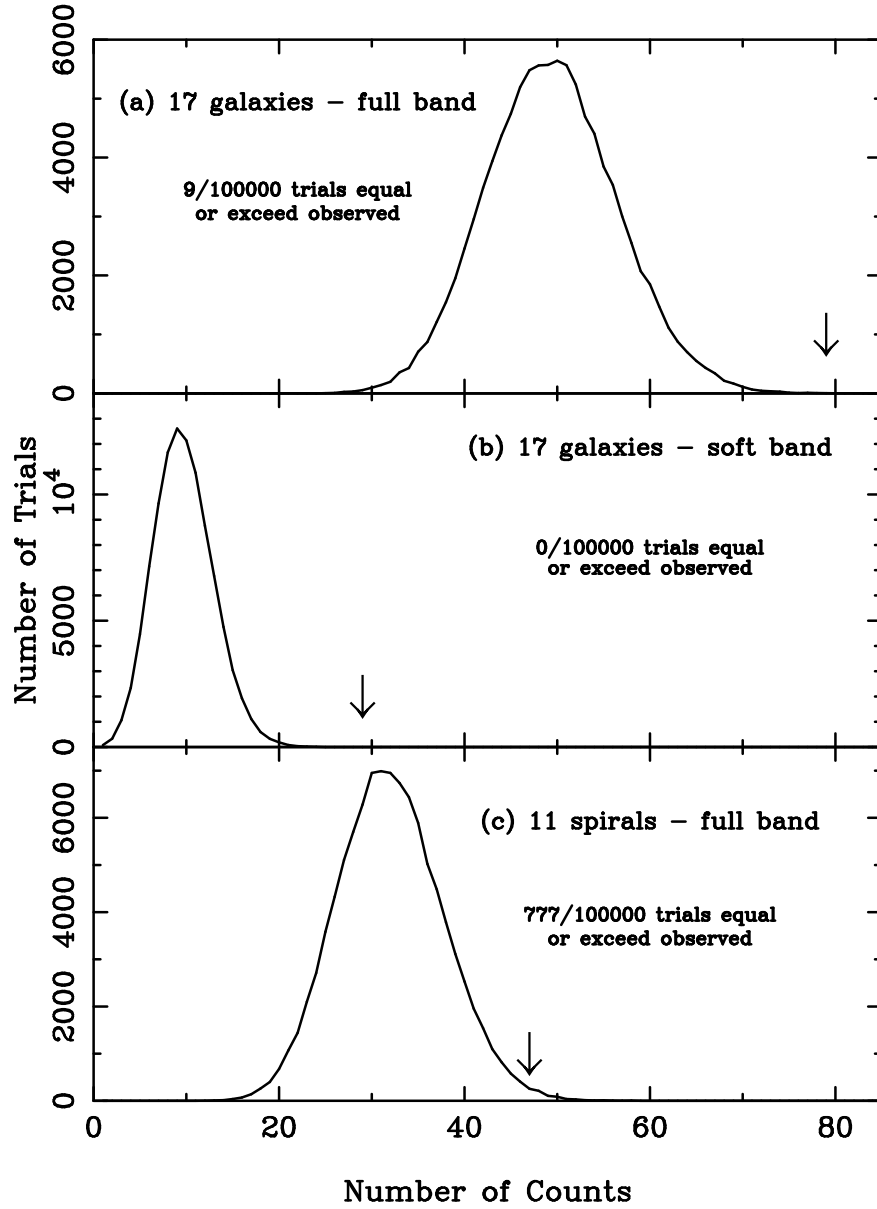

Fig. 11.— Results from our Monte-Carlo testing of the galaxy stacking analysis. In each panel, we have performed 100,000 stacking trials at randomly selected positions, and we plot the number of trials yielding a given number of counts in the 30-pixel source region described in §3.4.1. Arrows in each panel show the number of counts actually observed when the stated galaxies were stacked ( $N_{\text{obs}}$ ). Panel (a) is for the full-band stacking of the 17 galaxies in Table 4, panel (b) is for the soft-band stacking of the 17 galaxies in Table 4, and panel (c) is for the full-band stacking of the 11 spiral galaxies in Table 4. In each panel we also state the number of random trials yielding  $\geq N_{\text{obs}}$  counts.
